The effects of a nonzero photon rest mass can be incorporated into electromagnetism in a simple way using the Proca equations. In this vein, two interesting implications regarding the possible existence of a massive photon in nature, i.e., tiny alterations in the known values of both the anomalous magnetic moment of the electron and the gravitational deflection of electromagnetic radiation, are utilized to set upper limits on its mass. The bounds obtained are not as stringent as those recently found; nonetheless, they are comparable to other existing bounds and bring new elements to the issue of restricting the photon mass.

I. INTRODUCTION

In general, systems of heavy vector bosons are non-renormalizable. There are, however, two important exceptions to this rule: (i) gauge theories with spontaneous symmetry breakdown, and (ii) Abelian theories with neutral vectorial bosons coupled to conserved currents [1]. The latter, i.e., the ‘conserved current models’, contain at least one massive boson, whose source is conserved. These systems can be constructed through the following general prescription [2]:

- Begin with a Lagrangian which is invariant under a nonsemisimple group of local gauge transformations (i.e., a group containing an invariant Abelian subgroup).
- Arrange for spontaneous symmetry breaking (if any) such that the vacuum expectation value of the scalar field is invariant under at least one invariant (single-parameter) Abelian subgroup (thus, at this stage the corresponding Abelian vector is massless and coupled to a conserved current).
- Add (in the R gauge) an arbitrary mass term for the same Abelian vector.

Massive electrodynamics (or, Proca electrodynamics), i.e., the electrodynamics that can be embedded into the standard $SU(2) \times U(1)$ model and in which the photon has a small mass, is the simplest system of this type, besides being the most straightforward extension of standard QED. Indeed, Proca’s electromagnetic field theory can be constructed in a unique way by adding a mass

term to the Lagrangian for the electromagnetic field, namely,

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}^2 - J_\mu A^\mu + \frac{1}{2}m^2 A_\mu^2, \quad (1)$$

where $F_{\mu\nu} (= \partial_\mu A_\nu - \partial_\nu A_\mu)$ is the field strength, and J_μ is the (electric) current. The parameter m can be interpreted as the photon rest mass. In this spirit, the characteristic scaling length m^{-1} becomes the reduced Compton wavelength of the photon, which is the effective range of the electromagnetic interaction.

Massive QED is not only simpler theoretically than the standard theory [3], it also provides a fairly solid framework for analyzing (through the Proca equations) the far-reaching implications the existence of a massive photon would have for physics. Actually, some of these possible effects, such as variation of the speed of light, deviation in the behavior of static electromagnetic fields and longitudinal electromagnetic radiation, have been thoroughly studied by means of a number of different approaches over the past several decades [4–6]. It is worth mentioning that both the Aharonov-Bohm and the Aharonov-Casher effects are present in massive QED. The former was analyzed by Boulware and Deser [7] who showed that it reduces smoothly to the original result, while the latter was studied by Fuchs [8]. Nonetheless, the system of ‘Maxwell + photon mass + magnetic charge’ equations is not consistent [3, 4].

Interestingly enough, the possibility of a nonzero photon mass remains, as it was pointed out by Adelberger, Dvali, and Gruzinov [9], one of the most important issues in physics, as it would shed a new light on some fundamental questions, such as charge conservation, charge quantization, the possibility of charged black holes and magnetic monopoles. We also remark that the popular view that gauge invariance implies a zero photon mass is not correct. In reality, a minimal dynamics obeying gauge invariance, i.e., the Maxwell action, does imply

*Electronic address: accioly@cbpf.br

†Electronic address: helayel@cbpf.br

‡Electronic address: scatena@ift.unesp.br

zero photon mass; nevertheless, by enlarging the dynamics, for instance, by adding another field interacting with the photon field, both gauge invariance and nonzero mass can be accommodated simultaneously [6].

The purpose of this paper is to set upper bounds on the photon mass supposing that it is described by Proca electrodynamics. To accomplish this goal we shall analyze two interesting but not yet explored consequences of the possible existence of a massive photon in nature: the very small alteration in the usual anomalous magnetic moment of the electron and the tiny change in the ordinary gravitational deflection of the electromagnetic radiation. These issues are analyzed in detail in Secs. II and III, respectively. To conclude, a discussion about the order of magnitude of the bounds estimated in the aforementioned sections, is presented in Sec. IV.

In our conventions $\hbar = c = 1$, and the signature is $(+ - - -)$.

II. A QUANTUM BOUND

As is well-known, QED predicts the anomalous magnetic moment of the electron correctly to ten decimal places. Therefore, it is perfectly reasonable that we use this astonishing result, one of the great triumphs of QED, to estimate a quantum bound on the photon mass. How can we do that? By computing the anomalous magnetic moment of the electron to order α , where α is the fine structure constant, in the framework of massive QED and expanding afterward the result in powers of $(\frac{m}{\mu})^2$, where m and μ are, respectively, the photon and the electron masses. The first term of this expansion must necessarily coincide with that calculated by Schwinger in 1948 [10], while the second one is the most important correction related to the parameter m of massive QED. Now, taking into account that the latter must be less than 10^{-10} (the theoretical result predicted by QED for the anomalous magnetic moment of the electron [11] agrees in 1 part in 10^{10} with the experimental one [12]), we promptly find an upper bound for the photon mass.

Let us then perform the computations. We begin by recalling that the anomalous magnetic moment of the electron stems from the vertex correction for the scattering of the electron by an external field, as it is shown in Fig. 1.

For an electron scattered by an external static magnetic field and in limit $\mathbf{q} \rightarrow \mathbf{0}$, the gyromagnetic ratio is given by [13]

$$g = 2[1 + F_2(0)].$$

The form factor of the electron, $F_2(0)$, corresponds to a shift in the g -factor, usually quoted in the form $F_2(0) \equiv \frac{g-2}{2}$, and yields the anomalous magnetic moment of the electron.

On the other hand, from the quadratic part of Lagrangian (1) we immediately obtain the propagator for the massive QED, namely,

$$D_{\mu\nu} = -\frac{\eta_{\mu\nu}}{k^2 - m^2} + \frac{k_\mu k_\nu}{m^2(k^2 - m^2)}. \quad (2)$$

By employing this expression in the calculation of the diagram in Fig. 1, it can be shown that

$$F_2(0) = \frac{\alpha}{\pi} \int_0^\infty d\alpha_1 d\alpha_2 d\alpha_3 \delta(1 - \Sigma\alpha_i) \frac{\alpha_1(\alpha_2 + \alpha_3)}{(\alpha_2 + \alpha_3)^2 + \lambda^2\alpha_1},$$

where $\lambda^2 \equiv (\frac{m}{\mu})^2$. We remark that the term $\frac{k_\mu k_\nu}{m^2(k^2 - m^2)}$ that appears in Eq. (2) was omitted *ab initio* from the calculations concerning $F_2(0)$ because the propagator for the massive photon always occurs coupled to conserved currents.

In order to avoid unnecessary algebraic computations as far as the evaluation of $F_2(0)$ is concerned, we rewrite this expression as follows:

$$F_2(0) = X - Y,$$

where

$$X \equiv \frac{\alpha}{\pi} \int_0^\infty d\alpha_1 d\alpha_2 d\alpha_3 \delta(1 - \Sigma\alpha_i) \frac{\alpha_1}{\alpha_2 + \alpha_3}, \quad (3)$$

$$Y \equiv \frac{\alpha}{\pi} \int_0^\infty d\alpha_1 d\alpha_2 d\alpha_3 \delta(1 - \Sigma\alpha_i) \left[\frac{\alpha_1}{\alpha_2 + \alpha_3} - \frac{\alpha_1(\alpha_2 + \alpha_3)}{(\alpha_2 + \alpha_3)^2 + \lambda^2\alpha_1} \right]. \quad (4)$$

Integrating the expression (3) first with respect to α_3 and subsequently with respect to α_2 gives

$$\begin{aligned} X &= \frac{\alpha}{\pi} \int_0^1 d\alpha_1 \int_0^{1-\alpha_1} d\alpha_2 \frac{\alpha_1}{1-\alpha_1} \\ &= \frac{\alpha}{2\pi}. \end{aligned} \quad (5)$$

FIG. 1: Vertex correction for electron scattering by an external field.

Similarly, the expression (4) yields

$$\begin{aligned} Y &= \frac{\alpha}{\pi} \int_0^1 d\alpha_1 \frac{\lambda^2 \alpha_1^2}{(1 - \alpha_1)^2 + \lambda^2 \alpha_1} \\ &= \frac{\alpha}{\pi} \left[\lambda^2 - (\lambda^4 - 2\lambda^2) \ln \lambda \right. \\ &\quad \left. + \frac{\lambda^5 - 4\lambda^3 + 2\lambda}{\sqrt{4 - \lambda^2}} \arctan \frac{\sqrt{4 - \lambda^2}}{\lambda} \right]. \end{aligned} \quad (6)$$

From (5) and (6) we get

$$\begin{aligned} F_2(0) &= \frac{\alpha}{\pi} \left[\frac{1}{2} - \lambda^2(1 + 2 \ln \lambda) + \lambda^4 \ln \lambda \right. \\ &\quad \left. + \frac{4\lambda^3 - 2\lambda - \lambda^5}{\sqrt{4 - \lambda^2}} \arctan \frac{\sqrt{4 - \lambda^2}}{\lambda} \right]. \end{aligned} \quad (7)$$

Recalling that $\lambda \ll 1$, we arrive at the conclusion that

$$\begin{aligned} F_2(0) &\approx \frac{\alpha}{2\pi} \left[1 - \pi \left(\frac{m}{\mu} \right) - \left(\frac{3}{2} + 4 \ln \left(\frac{m}{\mu} \right) \right) \left(\frac{m}{\mu} \right)^2 \right. \\ &\quad \left. + \mathcal{O} \left(\left(\frac{m}{\mu} \right)^3 \right) \right]. \end{aligned} \quad (8)$$

As we have already commented, the first term in the above equation is equal to that calculated by Schwinger in 1948 (since then $F_2(0)$ has been calculated to order α^8 for QED), while the second one is the most important correction concerning the parameter m of massive QED. Since theory and experiment agree within errors to ~ 1 in 10^{10} for $F_2(0)$, we promptly obtain

$$\frac{\pi m}{\mu} < 10^{-10}, \quad (9)$$

implying $m < 1.6 \times 10^{-10} \text{ MeV}$.

Recently, the measurement of the anomalous magnetic moment of the muon reached the fabulous relative precision of 0.5 ppm [14, 15]. Accordingly, it would be interesting to find another quantum bound on the photon mass using this phenomenon and make afterward a comparison with the bound estimated via the electron. Now, taking into account that for the muon [16]

$$F_2^{(\text{exp})}(0) - F_2^{(\text{SM})}(0) = (295 \pm 88) \times 10^{-11},$$

where $F_2^{(\text{SM})}(0)$ denotes the prediction of the standard model [17], we find $m < 3.4 \times 10^{-7} \text{ MeV}$, three orders of magnitude higher than the bound derived from the anomalous magnetic moment of the electron. Consequently, we shall not consider this bound in our discussions.

III. A GRAVITATIONAL BOUND

It is a generally acknowledged fact that the gravitational deflection of light by the sun can be measured more accurately at radio wavelengths with interferometry techniques than at visible wavelengths with available optical techniques [18]. Indeed, at present the Very Long Baseline Interferometry (VLBI) is the most accurate technique we have at our disposal for measuring radio-wave gravitational deflection [19–21]. The gravitational bending, in turn, is one of the most impressive predictions of general relativity. In addition, the recent measurements of the gravitational bending of radio waves using the VLBI have improved considerable on the previous results in the gravitational bending experiments near the solar limb [22]. Accordingly, we shall use these results to estimate an upper limit on the photon mass. To do that we need, in first place, the unpolarized differential cross section for the scattering of a massive photon (described by Proca's electrodynamics) by an external weak gravitational field. On the other hand, it was recently shown that the unpolarized differential cross sections for the gravitational scattering of different quantum particles are spin dependent [23] (See Table I). Nonetheless, for small angles, the cross sections for the massive (massless) particles are one and the same, regardless of the spin. In fact, when the spin is 'switched off', i.e., for small angles ($\theta \ll 1$), it is fairly straightforward to see from Table I that for $m = 0$, $\frac{d\sigma}{d\Omega} \approx \frac{16G^2M^2}{\theta^4}$, while for $m \neq 0$, $\frac{d\sigma}{d\Omega} \approx \frac{16G^2M^2}{\theta^4} \left(1 + \frac{\lambda}{2}\right)^2$. In short, for small angles the results of Table I are in perfect agreement with those predicted by Einstein's geometrical theory. Consequently, the differential cross section we are searching for is independent of the spin of the massive particle and can be written as

$$\frac{d\sigma}{d\Omega} = \frac{16G^2M^2}{\theta^4} \left(1 + \frac{\lambda}{2}\right)^2. \quad (10)$$

The above differential cross section can be related to a classical trajectory with impact parameter b via the relation

$$bdb = -\frac{d\sigma}{d\Omega} \theta d\theta. \quad (11)$$

From (10) and (11), we arrive at the conclusion that

$$\theta = \frac{4MG}{b} \left(\frac{1 - \frac{m^2}{2E^2}}{1 - \frac{m^2}{E^2}} \right), \quad (12)$$

which in the ultrarelativistic limit, i.e., $E \gg m$, reduces to

$$\begin{aligned} \theta &= \theta_E \left(1 + \frac{m^2}{2E^2} \right), \\ &= \theta_E \left(1 + \frac{m^2}{8\pi^2\nu^2} \right), \end{aligned} \quad (13)$$

where E and ν are, respectively, the energy and the frequency of the ingoing massive photon, and $\theta_E \equiv \frac{4MG}{b}$.

TABLE I: Unpolarized differential cross sections for the scattering of different quantum particles by an external weak gravitational field generated by a static point particle of mass M . Here m is the particle mass, s the spin, θ the scattering angle, G the Newtonian constant, and $\lambda \equiv \frac{m^2}{\mathbf{p}^2} = \frac{1-\mathbf{v}^2}{\mathbf{v}^2}$, with $\mathbf{v}$ and $\mathbf{p}$ being the velocity and three-momentum, in this order, of the incident particle.

m	s	$\frac{d\sigma}{d\Omega}$
0	0	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2$
$\neq 0$	0	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2 \left(1 + \frac{\lambda}{2}\right)^2$
0	$\frac{1}{2}$	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2 \cos^2 \frac{\theta}{2}$
$\neq 0$	$\frac{1}{2}$	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2 \left[\cos^2 \frac{\theta}{2} + \frac{\lambda}{4} \left(1 + \lambda + 3 \cos^2 \frac{\theta}{2}\right)\right]$
0	1	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2 \cos^4 \frac{\theta}{2}$
$\neq 0$	1	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2 \left[\frac{1}{3} + \frac{2}{3} \cos^4 \frac{\theta}{2} - \frac{\lambda}{3} \left(1 - \frac{3\lambda}{4} - 4 \cos^2 \frac{\theta}{2}\right)\right]$
0	2	$\left(\frac{GM}{\sin^2 \frac{\theta}{2}}\right)^2 \left(\sin^8 \frac{\theta}{2} + \cos^8 \frac{\theta}{2}\right)$

The first term in the expression (13) coincides with that obtained by Einstein in 1916 by solving the equation of light propagation in the field of a static body [24], whereas the second one is the most important correction due to the mass m of the massive photon. On the other hand, the angle of gravitational bending measured by the experimental groups is expressed in general through the relation [25]

$$\theta_{\text{exp}} = \frac{1+\gamma}{2}\theta_E, \quad (14)$$

where γ is the deflection parameter characterizing the contribution of space curvature to gravitational deflection. From Eqs. (13) and (14), we then get

$$\theta_E \frac{m^2}{8\pi^2\nu^2} < \theta_E \left(1 - \frac{1+\gamma}{2}\right), \quad (15)$$

implying

$$m < 2\pi\nu\sqrt{1-\gamma}. \quad (16)$$

Not long ago, Fomalont *et al.* [22] determined the deflection parameter $\gamma = 0.9998 \pm 0.0003$ (68% confidence

level), using the VLBI at 43, 23 and 15 GHz to measure the solar gravitational deflection of radio waves. Their results come mainly from 43 GHz observations where the refraction effects of the solar corona were negligible beyond 3 degrees from the sun [26].

Using the result for the deflection parameter found by Fomalont *et al.* and assuming that the massive photon passing near the solar limb has a frequency $\nu = 43 \text{ GHz}$ (which is perfectly justifiable in view of the argument previously provided), we conclude that $m < 3.5 \times 10^{-11} \text{ MeV}$.

We remark that Eq. (12) can also be deduced *à la Einstein*, namely, by finding an approximate solution to the geodesic equation of motion of a massive test particle in the Schwarzschild field. By adopting this approach, an expression for the angle of particle deflection by the sun was obtained to order $\left(\frac{GM}{b}\right)^3$ in Ref. 27. This kind of deduction, however, is a time-consuming work. On the other hand, Golowich, Gribovsky, and Pal [28], instead of taking the usual geometrical approach, considered the phenomenon of light bending as a quantum scattering problem. This treatment, which is not only instructive but also straightforward when the gravitational field is weak, allowed them to easily obtain an expression for the gravitational deflection of massive particles to order $\frac{GM}{b}$. An identical result was found by Mohany, Nieves, and Pal [29] using a method pioneered by Ohanian and Ruffini [30].

At this point, some comments are in order.

- According to general relativity, photons are not only deflected but also delayed by the curvature of space-time produced by any mass. And more, the bending and delay are proportional to $\gamma + 1$. Consequently, time delay techniques can also be employed to set up bounds on the photon mass. It is interesting to note that a few years ago, Bertotti, Iess, and Tortora [31] reported a measurement of the frequency shift of radio photons to and from the Cassini spacecraft as they passed near the sun that led to a result for γ which agrees with the predictions of standard general relativity with a sensitivity that approaches the level at which, theoretically, deviations are expected in some cosmological models [32, 33].
- Equation (13) was derived on the assumption that the field responsible for the photon deflection is a static gravitational field. Nonetheless, as well-known, neither the sun nor the planets are at rest in the solar system. Actually, they are moving with respect to both the barycenter of the solar system and the observer. This motion will certainly bring about velocity-dependent corrections to the general-relativistic equation of the gravitational deflection of light. As a consequence, the aforementioned motion-induced correction to the gravitational deflection of light shall correlate with the correction to the photon's mass exhibited in

equation (13). This fact leads us to pose an important question: Currently, is modern technology sensitive enough to detect these tiny relativistic effects caused by the dependence of the gravitational field on time? Kopeikin [34] claims that ‘future gravitational light-ray deflection experiments [35], radio ranging BepiColombo experiment [36], laser ranging experiments ASTROD [37] and LATOR [38] will definitely reach the precision in measuring $\bar{\gamma}_{\text{PPN}}$, $\bar{\beta}_{\text{PPN}}$ and $\bar{\delta}_{\text{PPN}}$ that is comparable with the post-Newtonian corrections to the static time delay and to the deflection angle caused by the motion of the massive bodies in the solar system [39].’ Here, deviation from general relativity are denoted with the comparative PPN parameter $\bar{\gamma}_{\text{PPN}} \equiv \gamma_{\text{PPN}} - 1$, $\bar{\beta}_{\text{PPN}} \equiv \beta_{\text{PPN}} - 1$ and $\bar{\delta}_{\text{PPN}} \equiv \delta_{\text{PPN}} - 1$. On the other hand, one can show, using the equation for the post-post-Newtonian time delay, Δt , which was obtained by Kopeikin by coupling the PPN parameters with the velocity-dependent terms, that for gravitational experiments with light propagating in the field of the sun,

$$\Delta t \approx (1 + \bar{\Gamma}) \ln \left(\frac{r_1 + r_2 + r_{12}}{r_1 + r_2 - r_{12}} \right), \quad (17)$$

with

$$\bar{\Gamma} \approx \bar{\gamma}_{\text{PPN}} - 2\beta_{\odot}, \quad (18)$$

where $\beta_{\odot}$ ($= 5.3 \times 10^{-8}$) is the solar velocity (in natural units) with respect to the barycenter of the solar system, r_{12} is the coordinate distance between the emission and observation points, r_1 , r_2 are radial distances to the emission and observation points, respectively. Now, noticing that the LATOR and ASTROD space missions are going to measure the $\bar{\gamma}_{\text{PPN}}$ parameter with a precision approaching to 10^{-9} [37, 38], we arrive at the conclusion that in the near-future, the explicit velocity-dependent correction to the static time delay in the solar gravitational field must apparently be taken into account. Let us then answer the question raised above. For the sake of simplicity we restrict our discussion to measurements of light bending by the sun obtained through VLBI techniques. Currently the experimental groups have determined the parameter $\bar{\gamma}_{\text{PPN}}$ using the VLBI with an accuracy of 10^{-4} [22]. Therefore, the alluded velocity-dependent correction is too small and can be neglected in the determination of $\bar{\gamma}_{\text{PPN}}$. Actually, the detection of so small an effect is beyond current technology.

- Nowadays, as we have already pointed out, the VLBI is the most accurate technique we have

at our disposal for measuring radio-wave gravitational deflection on a regular basis [19–21]. It was only superseded by the multiple frequency Doppler-tracking of Cassini spacecraft [31].

- Measuring light deflection with optical techniques may turn out more advantageous for determining the parameter γ in a foreseeable future [40].

IV. DISCUSSION

We discuss now whether or not the bounds we have found could be improved. To begin with, we consider the quantum limit. A quick glance at Eq. (9) clearly shows that a better agreement between theory and experiment concerning the anomalous magnetic moment of the electron necessarily leads to an improvement on the quantum bound. Consequently, there is a great probability of obtaining a better quantum bound on the photon mass in the foreseeable future. We analyze in the sequel how a better limit on the photon mass might be obtained using Eq. (16). First, if the deflections measured using the VLBI could be made with greater accuracy the value of $\sqrt{|1 - \gamma|}$ would be reduced giving, as a result, a better gravitational estimate. According to Fomalont *et al.* [22], a series of designed experiments with the VLBI could increase the accuracy of the future experiments by at least a factor of 4. Second, if deflection measurements can be obtained at lower frequencies, while maintaining the value of the deflection parameter γ , the gravitational bound will be improved in direct proportion to the frequency. This point, however, needs to be dealt with carefully. In fact, as we have already mentioned, up till now the best results obtained for the gravitational deflection via the VLBI are those that come mainly from 43GHz where the refraction effects of the solar corona are negligible beyond 3 degrees from the sun. Incidentally, the lowest frequency employed by the radio astronomers was 2GHz . However, the measurements made at this frequency are less reliable because of the refraction effects of the solar corona. Actually, the radio astronomers use in their experiments a mixing of different frequencies but the most significant contributions come in general from $\sim 43\text{GHz}$. This possibility of increasing the gravitational limit is thence very limited.

Certainly, the bounds we have found on the photon mass are higher than the recently recommended limit published by the Particle Data Group [12]. They are nevertheless comparable to other existing bounds (See Table II) and bring new elements to the issue of restricting the photon mass. Accordingly, they do have some merits. We discuss their main qualities in the following.

- The theory adopted to describe the photon mass has the correct limit.
- The bounds are based on exact calculations performed in the framework of QED and general rela-

TABLE II: Some upper bounds on the photon mass obtained by measuring the dispersion in the speed of light in different ranges of the electromagnetic spectrum (in chronological order).

Author (year)	Type of measurement	Limits on m (MeV)
Froome (1958)[41]	Radio-wave interferometer	2.4×10^{-13}
Warner <i>et al.</i> (1969)[42]	Observations on Crab Nebula pulsar	2.9×10^{-14}
Bay <i>et al.</i> (1972)[43]	Pulsar emission	1.7×10^{-19}
Brown <i>et al.</i> (1973)[44]	Short pulses radiation	7.9×10^{-7}
Schaefer (1999)[45]	Gamma ray bursts (GRB980703)	2.4×10^{-17}
	Gamma ray bursts (GRB930229)	3.4×10^{-12}

tivity, respectively; besides, the most accurate experimental data currently available have been taken as input.

- The conceptual approaches adopted to estimate the bounds are new.
- The methods used for placing the bounds are interesting in their own, although they do not lead to the most stringent limits. Indeed, the quantum bound is estimated using one of the most renowned predictions of QED — the anomalous magnetic moment of the electron, while the gravitational bound is obtained using the properties of gravity. Essentially, the point is that a massive photon is bent in a gravitational field by a different amount than a massless photon. Thus, observations of light bending by the sun allow one to place limits on the photon mass.
- The bounds are essentially a measurement of the agreement between theory and experiment. Since

the two limits are of the same order, they may be used to give an idea of how much the theoretical prediction deviates from the experimental result. For the quantum and semiclassical bounds we have estimated this lower limit is $m^{-1} \sim 2cm$. Thus, the more the value of m^{-1} increases, the more the concordance between theory and experiment increases. In other words, a null mass for the photon would imply a perfect agreement between theory and experiment

- Recently, Adelberger, Dvali, and Gruzinov [9] questioned the validity of some bounds on the photon mass available in the literature. They claim that if m arises from a Higgs effect, these limits are invalid because the Proca vector potential of the galactic magnetic field may be neutralized by vortices giving a large-scale magnetic field that is effectively Maxwellian. However, these criticisms do not apply to our computations because they are based on the plausible assumption of large galactic vector potential; furthermore, in our case m does not arise from a Higgs effect.

Last but not least, we would like to draw the reader's attention to the article by Barton and Dombey [46] in which it is demonstrated that the Casimir effect is not sensitive to a small photon mass. To accomplish this, they showed that the contribution to the Casimir force due to the photon mass is proportional to m^4 , being, as a consequence, negligible compared with the leading finite-mass correction to the contribution from the transverse modes. On the other hand, if the galactic magnetic field is in the Proca regime, the very existence of the observed large-scale magnetic field gives $m \sim 10^{-26}eV$ [9]. Therefore, the electron anomalous magnetic moment and the deflection of light by the sun, like the Casimir effect, are insensitive to a photon mass less than the allowed already established limits.
